Studies on the Hydrolysis of Metal Ions

39. The Hydrolysis of Pb$^{2+}$ in Mg(ClO$_4$)$_2$ and Ba(ClO$_4$)$_2$ Medium

LECH PAJDOWSKI* and ÅKE OLIN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of Pb$^{2+}$ in 1.5 M Mg(ClO$_4$)$_2$ or Ba(ClO$_4$)$_2$ has been studied by emf methods. In both media the hydrolysis products Pb$_4$OH$^{3+}$ and Pb$_4$(OH)$_4$$^{4+}$ have been identified. These complexes have also been found in a previous investigation$^1$ with 3 M NaClO$_4$ as salt back-ground. From an analysis of the results at high concentrations of Pb$^{2+}$ it is inferred that the self-medium method of Hietanen and Sillén$^2$ can yield reliable results in a region where as much as up to 10% of the free metal ions have been changed to hydrolysis products.

The hydrolysis products of many metal ions have been identified in dilute solution by emf methods$^3$. The measurements have been made with solutions containing a high salt back-ground, usually 3 M NaClO$_4$. In such solutions the activity factors vary but little, which is a necessary condition for the successful identification of the complexes formed.

When a metal ion forms polynuclear hydrolysis products, the relative amounts of the species formed will depend both on the total concentration of the metal ion, $B$, and on the concentration of hydrogen ion, $h$. It is therefore possible that in concentrated solutions of the metal salt new complexes appear, whose concentrations at low $B$ are so small that they cannot be identified.

The self-medium method proposed by Hietanen and Sillén$^2$ can be used to identify the hydrolysis products at high values of $B$. However, from such studies, reliable results can be expected only from measurements with small ranges in $Z$, since otherwise the variation in the composition of the solutions and hence in the activity factors, may become so large that it will interfere with the interpretation of the data.

Self-medium studies$^{1,4}$ on Be$^{2+}$ and Pb$^{2+}$ in 3 M (Na)ClO$_4$ medium have indicated that reliable results can be obtained if the investigation is confined to the $Z$ range 0 < $Z$ < 0.1. The species identified were Be$_2$OH$^{3+}$ and Be$_3$(OH)$_3$$^{3+}$, and Pb$_2$+, Pb$_2$OH$^{3+}$ and Pb$_4$(OH)$_4$$^{4+}$. For higher values of $Z$, deviations occurred between the experimental data ($Z$, log $h$) and those calculated on the assumption that the above-mentioned complexes were

* Present address: Department of Inorganic Chemistry, University of Wroclaw, Poland.
formed. Two possible explanations for this were suggested; the formation of other complexes, or the variation of activity factors.

The present investigation was undertaken in an effort to obtain more information on this point. If substantial changes are found in the shapes of the curves $Z(\log h)_B$ with different media it appears reasonable to ascribe the cause of the deviation to changes in the activity factors and not to new complexes. It should, however, be observed that we can not choose unequivocally between the two hypotheses. The Pb$^{2+}$ ion was used in this study, since Pb(ClO$_4$)$_2$ solutions are easy to analyze for their analytical hydrogen ion excess, which is essential if accurate values of $Z$ are to be obtained. As salt back-grounds Mg(ClO$_4$)$_2$ and Ba(ClO$_4$)$_2$ have been used.

**SYMBOLS**

$B =$ total metal ion concentration; $b =$ free metal ion concentration; $H =$ analytical hydrogen ion excess (often negative); $h =$ free hydrogen ion concentration; $Z =$ average number of OH$^-$ bound per metal ion $= (h - H)/B$; $\beta_{P,H} =$ equilibrium constant of the reaction $pA + qB \rightleftharpoons A_pB_q; y(x)_v = y$ as a function of $x$ at constant $v$.

Concentrations are expressed in moles/l (M) and equilibrium constants are given on the M-scale.

**MATERIALS AND ANALYSES**

Magnesium and barium perchlorate were prepared by reacting MgCO$_3$ and Ba(OH)$_2$ (Merck p.a.) with HClO$_4$ (Kobo p.a.). The products were twice recrystallized from water. The stock solutions of Mg(ClO$_4$)$_2$ and Ba(ClO$_4$)$_2$ were analysed by evaporating known quantities with H$_2$SO$_4$ and weighing the residues as MgSO$_4$ and BaSO$_4$. The neutrality of these solutions was checked potentiometrically as described in Ref. 4.

The "basic" lead perchlorate stock solution was prepared from PbO (Baker p.a.), which had been repeatedly washed with distilled water, and perchloric acid. An excess of the oxide was used and the mixture of oxide and solution was allowed to stand for a couple of days in order to precipitate foreign metal ions. The solution was then filtered and traces of tetravalent lead removed by bubbling H$_2$ through the solution using platinum black as a catalyst. Finally the solution was filtered in a N$_2$ atmosphere and then stored and handled under the same gas. The Pb$^{2+}$ concentration in this solution was found by precipitating lead as PbSO$_4$ and the analytical hydrogen ion excess, which is a negative quantity in this solution, was determined potentiometrically using Gran's method to obtain the equivalence point.

The "neutral" lead perchlorate solution was prepared from stoichiometric amounts of PbO and HClO$_4$. It was analysed in the same way as the "basic" lead perchlorate solution.

**EXPERIMENTAL**

The experiments were carried out as potentiometric titrations, at 25.0°C, in an oil thermostat. The hydrogen ion concentration, $h$, was measured with a calibrated glass electrode and using the cell

$$\text{glass electrode/equilibrium solution/Ref.}$$

Assuming the activity factors to be constant the emf of cell (I) can be written

$$E = E^o - 59.15 \log h - E_j$$

The equilibrium solutions had the following composition

$$B M \text{ Pb}^{2+}, H M \text{ H}^+, (3-2B-H)/2 M \text{ (Mg}^{2+}, \text{ Ba}^{2+}), 3 M \text{ ClO}_4^-$$

*Acta Chem. Scand. 16 (1962) No. 4*
and the reference half-cell used was

\[ 1.5 \text{ M (Mg}^{2+}, \text{Ba}^{++}) \text{(ClO}_4\text{)}_2/3 \text{ M ClO}_4\text{, }1.495 \text{ M (Mg}^{2+}, \text{Ba}^{++}), \text{0.01 M Ag}^+ / \text{AgCl, Ag} \] (II)

In each experiment \( B \) and \([\text{ClO}_4^-]\) = M were kept constant and \( H \) was varied by the addition of a hydrolysed lead perchlorate solution or by the addition of HClO\(_4\). The emf of cell (I) was measured with a Radiometer valve potentiometer (PHM 4) to \( \pm 0.2 \text{ mV} \).

**Titration procedure.** Two different titration procedures were used depending on the value of \( B \). With \( B = 0.05 \text{ M} \) and \( 0.1 \text{ M} \) three solutions were used, each 3 M in \text{ClO}_4\ by addition of the ionic medium;

- S\(_1\): The "starting" solution, containing \( B \text{ M Pb(ClO}_4\text{)}_2 \).
- S\(_2\): The "basic" solution, containing \( B \text{ M PbOHClO}_4 \).
- S\(_3\): The "acid" solution, containing \( B \text{ M Pb(ClO}_4\text{)}_2 \) and \( H \text{ M HClO}_4 \).

Solution \( S_0 \), \( V \text{ ml} \), was gradually added from a buret to a known volume, \( V_0 \text{ ml} \), of the "starting" solution, \( S_1 \), and the emf of cell(I) was measured after each addition ("basic titration"). When the desired volume of \( S_0 \) had been added, then solution \( S_3 \) was introduced in order to give values of \( H \) between 0.005 and 0.025 M ("acid titration").

The values of \( E \) measured in the acid titration were used to determine the analytical hydrogen ion concentration (\( H_b \)) in the basic lead solution, \( S_0 \), by Gran’s method. \( H \) was then calculated from the analytical data for each point in the acid titration and \( E^0 \) determined from a plot of \( E' = E + 59.15 \log H \) versus \( H \). The straight line \( (E + 59.15 \log H) \) was extrapolated to \( H = 0 \) to give \( E^0 \) (Ref.7).

With \( E^0 \) known from the acid titration log \( h \), \( H \) and \( Z \) in the basic titration can be calculated from

\[ \log h = (E^0 - E)/59.15 \] (2)
\[ H = H_b V/(V_0 + V) \] (3)
\[ Z = (h - H)/B \] (4)

At the higher \( \text{Pb}^{2+} \) concentrations, \( B \geq 0.25 \text{ M} \), only two solutions were used. To the starting solution, \( V_0 \text{ ml} \), containing \( B \text{ M Pb(ClO}_4\text{)}_2 \) and a known amount of HClO\(_4\) (ca. 0.025 M), \( V \text{ ml} \) of basic lead solution, \( S_0 \), were added from a buret. The first few points in the acid solution were used to determine the analytical hydrogen ion excess in \( S_0 \) and \( E^0 \). Two basic solutions were employed. One solution had a OH\(^-\)/ClO\(_4\) ratio equal to 1 and the other had a lower OH\(^-\)/ClO\(_4\) ratio so that accurate results could be obtained at low \( Z \). In these titrations log \( h \) was found from eqn. (2) and \( H \) from

\[ H = H_b(V - V_e)/(V_0 + V) \] (5)

where \( V_e \) denotes the equivalence point from the Gran extrapolation. \( Z \) was calculated from eqn. (4).

All solutions were carefully protected against CO\(_2\) and were mixed and handled under a \( N_2 \) atmosphere. If severe precautions were not taken and CO\(_2\) came into contact with the solution this resulted in the precipitation of lead hydroxide carbonates.

**RESULTS AND CALCULATIONS**

The experimental data, \( Z \) and log \( h \), are presented in Fig. 1 and Table 1. With Ba(ClO\(_4\))\(_2\) as medium the following values of \( B \) were used; \( B = 0.05 \), 0.1, 0.25, 0.5, 1, and 1.45 M. With Mg(ClO\(_4\))\(_2\) titrations with \( B = 0.05 \), 0.5, 1, and 1.45 M were made. Two titrations with NaClO\(_4\) as medium were performed also and they agreed within 0.3 mV with previously published titrations 4, where NaOH was used as the base, and are therefore not included in Table 1.

*Acta Chem. Scand.* 16 (1962) No. 4
Fig. 1. Z, average number of OH\(^{-}\) bound per Pb(II) atom as a function of log h. Drawn curves have been calculated with the equilibrium constants given in the text.

From the data we observe that for \( B \leq 0.25 \) M the curves are parallel and considering the data with Ba(ClO\(_4\))\(_2\) medium only, \( t = (\Delta \log B/\Delta \log h)_Z \) is found to be a constant = 1.33 ± 0.02.

From the data with \( B \geq 0.5 \) M it is found that the shifts between the curves \( Z(\log h)_B \) for the different media tend to diminish as \( B \) increases. This is particularly obvious with \( B = 1.45 \) M for \( Z < 0.05 \). In this range the curves coincide. This is of course due to the fact the compositions of the solutions tend to become the same, namely Pb(ClO\(_4\))\(_2\), as \( B \) increases and \( Z \) decreases. As \( Z \) increases the curves \( Z(\log h)_B \) in the three media become separate and the values of \( l = |(\Delta Z/\Delta \log h)_B| \) for a given value of \( Z \), always follow the order \( l \) (in NaClO\(_4\)) < \( l \) (in Ba(ClO\(_4\))\(_2\)) < \( l \) (in Mg(ClO\(_4\))\(_2\)).

Identification of the Complexes Formed at \( B \leq 0.25 \) M.

As stated above the value of \( (\Delta \log B/\Delta \log h)_Z = 1.33 \pm 0.02 \) for \( B \leq 0.25 \) M in 1.5 M Ba(ClO\(_4\))\(_2\) medium. The composition of the complexes formed can then, according to Sillén \(^8\), be written Pb(Pb(OH)\(_{3+n}\))\(_{2n+4}^{2+}\). Conceivable values of \( n \) are obtained from the relation \( n = 3 m \) with \( m = 1, 2, 3 \ldots \). With \( n = 3 \), which means that the complex Pb\(_4\)(OH)\(_4\)^{4+} is formed, an excellent fit was found between the experimental curves Z(\log h)\(_B\) and the "normalized" curve for the formation of Pb\(_4\)(OH)\(_4\)^{4+}. The formation of Pb\(_4\)(OH)\(_4\)^{4+} was

*Acta Chem. Scand.* 16 (1962) No. 4
confirmed by the "integration method" derived by Silén. This method gave invariant values of $\bar{p}$ and $\bar{q} = 4$. $\bar{p}$ and $\bar{q}$ are the average values of $p$ and $q$ of the complexes $\text{Pb}_4(\text{OH})_{4(2+)}^+ \text{Pb}_3(\text{OH})_{2(2+)} \text{Pb}^{2+}$ formed. The formation of $\text{Pb}_4(\text{OH})_{4(2+)}^+$ in 1 M $\text{Ba(ClO}_4)_2$ is thus well established. The same complex has also been found in 3 M NaClO$_4$ medium. In 1.5 M Mg(ClO$_4$)$_2$ it is also likely that the same complex is formed to judge from the good agreement between the experi-

*Acta Chem. Scand.* 16 (1962) No. 4
mental \( Z(\log h) \) curve for \( B = 0.05 \text{ M} \) and the normalized curve. This conclusion is confirmed by the results from the titrations with \( B \geq 0.5 \text{ M} \) in this medium.

With \( B = 0.05 \text{ M} \), measurements have been made with all the three media and we observe three \( Z(\log h) \) curves which are parallel along the \( \log h \) axis. The shifts between the curves can be understood, if the activity factors stay constant in each medium but are different from one medium to another.

**IDENTIFICATION OF THE COMPLEXES FORMED AT \( B \geq 0.5 \text{ M} \)**

 Whereas for \( B \leq 0.25 \text{ M} \) the formation of the complex \( \text{Pb}_4(\text{OH})^4_4 \) can explain the experimental data, additional complexes must be present for \( B \geq 0.5 \text{ M} \) at low values of \( Z \). This is indicated by the fact that \( (\Delta \log B/\Delta \log h)_2 \) at low \( Z \) is no longer 1.33 but tends to diminish with increasing \( B \) and that the curves \( Z(\log h)_B \) fall off to zero less rapidly than required for the \( -\text{(OH)}^4_4 \) complexes.

 The values of \( p \) and \( q \) of the complexes formed at low \( Z \), \( \text{Pb}_4(\text{OH})_p^{(2q-p)} \), can be estimated from the relations \( p = -(\Delta \log Z/\Delta \log h)_B \) and \( q = (\Delta \log Z/\Delta \log B)_A + 1 \), as described in Ref.\(^1\) When the present data for \( 0 < Z < 0.01 \) were treated as described there, they yielded \( p = 1 \) and \( q = 2 \). The new complex formed at low \( Z \) would then be \( \text{Pb}_3\text{OH}^3_3 \). The "integration method" was next applied to all the data and an example of the results is shown in Fig. 2. From this graph we may conclude that the main complexes formed are \( \text{Pb}_3\text{OH}^3_3 \) and \( \text{Pb}_4(\text{OH})^4_4 \). It is thus established that in \( \text{NaClO}_4 \), \( \text{Mg(ClO}_4)_2 \) and \( \text{Ba(ClO}_4)_2 \) medium the main hydrolysis products are the same.

**DETERMINATION OF THE EQUILIBRIUM CONSTANTS**

 From the data with \( B \leq 0.25 \text{ M} \) only the equilibrium constant for the formation of \( \text{Pb}_4(\text{OH})^4_4 \)

\[
4 \text{Pb}^2_4 + 4 \text{H}_2\text{O} \rightleftharpoons \text{Pb}_4(\text{OH})^4_4 + 4 \text{H}^+ \tag{6}
\]

\[
\beta_{4,4} = [\text{Pb}_4(\text{OH})^4_4] \text{H}^4/\text{b}^4 \tag{6a}
\]

can be determined, since the concentration of \( \text{Pb}_3\text{OH}^3_3 \) is so small. The determination of \( \beta_{4,4} \) has been made by graphical methods using a "normalized" curve, which can be derived from the two basic equations

\[
B = b + 4[\text{Pb}_4(\text{OH})^4_4] \tag{7}
\]

\[
\text{BZ} = h - H = 4[\text{Pb}_4(\text{OH})^4_4] \tag{8}
\]

If \( b \) is eliminated we obtain

\[
X = \log h - 0.25 \log (4\beta_{4,4}B^3) = \log (1 - Z) - 0.25 \log Z \tag{9}
\]

In position of best fit between the normalized curve \( Z(X) \) and the experimental curve \( Z(\log h)_B \) the difference between the coordinates on the \( X \)- and \( \log h \)-axes = \(-0.25 \log(4\beta_{4,4}B^3) \) which is used to find \( \beta_{4,4} \). The values of \( \log \beta_{4,4} \) so obtained are given below.

*Acta Chem. Scand.* 16 (1962) No. 4
HYDROLYSIS OF METAL IONS 39

Fig. 2. \( \bar{p} \) versus \( \bar{q} \) for \( B = 1 \) M. The straight line passes through (2,1) and (4,4).

Ba(ClO₄)₂: \( \log \beta_{4,4} = -19.16 \pm 0.05 \) (\( B = 0.05, 0.1 \) and 0.25 M)
Mg(ClO₄)₂: \( \log \beta_{4,4} = -18.90 \pm 0.05 \) (\( B = 0.05 \) M)

For \( B \geq 0.5 \) M the complexes \( \text{Pb}_2 \text{OH}^{3+} \) and \( \text{Pb}_4(\text{OH})_4^{4+} \) have definitely been identified. The determination of the equilibrium constants \( \beta_{1,2} \) and \( \beta_{4,4} \) was therefore started on the assumption that only these two complexes were formed. The agreement between the calculated and experimental \( Z(\log h)_B \) curves will then show if this hypothesis is correct or has to be modified.

A first set of values of \( \beta_{1,2} \) and \( \beta_{4,4} \) (necessary for further calculations with electronic computer programs) was obtained as follows

\[
BZ = \beta_{1,2} b^2 h + 4 \beta_{4,4} b^4 h^{-4}
\] (10)

In this expression \( b \) is approximated with

\[
b = B(1-2Z) \text{ for } Z < 0.01 \text{ and } b = B(1-Z) \text{ for } Z > 0.01
\]

Inserting these values for \( b \) in eqn. (10) and rearranging we obtain for \( Z < 0.01 \)

\[
Z h/(1-2Z)^2 = B \beta_{1,2} + 4 \beta_{4,4} B^3 (1-2Z)^2 h^{-3}
\] (12a)

and for \( Z > 0.01 \)

\[
Z h/(1-Z)^2 = B \beta_{1,2} + 4 \beta_{4,4} B^3 (1-Z)^2 h^{-3}
\] (12b)

The plots of eqn. (12a), (12b) for the data with Mg(ClO₄)₂ medium were straight lines as required by the hypothesis. With Ba(ClO₄)₂ medium, however, the lines were curved for \( Z > (0.1-0.2) \), the actual value of \( Z \) being somewhat dependent on the value of \( B \).

The equilibrium constants found from the plots were used as first approximations in the final adjustment of the constants. This adjustment was done by means of the computer program LETAGROP. The best set of constants found with this program is that, which makes \( \Sigma(Z_{\text{exp}} - Z_{\text{calc}})^2 \) a minimum. The following values of the equilibrium constants were obtained for the \( Z \)

Acta Chem. Scand. 16 (1962) No. 4
ranges given in the table. The limits of error given in the log $\beta$ are three times
the standard deviation.

\[
\begin{array}{cccc}
B & Mg(ClO_4)_2 & Z & Ba(ClO_4)_2 & Z \\
0.5 M & \log \beta_{1,2} = -6.49 \pm 0.09 & <0.3 & -6.30 \pm 0.2 & <0.26 \\
& \log \beta_{2,4} = -18.949 \pm 0.003 & & -19.12 \pm 0.02 & \\
1 M & \log \beta_{1,2} = -6.57 \pm 0.09 & <0.25 & -6.39 \pm 0.06 & <0.12 \\
& \log \beta_{2,4} = -18.978 \pm 0.003 & & -19.11 \pm 0.01 & \\
1.45 M & \log \beta_{1,2} = -6.45 \pm 0.06 & <0.25 & -6.24 \pm 0.06 & <0.12 \\
& \log \beta_{2,4} = -19.045 \pm 0.003 & & -19.12 \pm 0.02 & \\
\end{array}
\]

**DISCUSSION**

With $B = 1.45$ M the two media are almost identical and we should therefore
expect the $\beta$ also to be the same. The fact that two different sets of $\beta$
are obtained arises from the principle used in selecting the best values of $\beta$,
namely to find the values of $\beta$ which reproduce the experimental $Z$ values
over as broad a $Z$ range as possible with the restriction that $|Z_{\text{exp}} - Z_{\text{calc}}|
should not exceed 0.002 systematically in any part of the range. The standard deviation
in $Z$ is less than 0.001 for the data in the table. If the calculations
on the $Ba(ClO_4)_2$ data are restricted to the range $Z < 0.05$, values of $\beta$
are obtained which are closer to the $\beta$ values with $Mg(ClO_4)_2$ medium. The
same is true of the older data with NaClO$_4$ medium for $B = 1.49$ M. We
should like here to correct the values given in Ref.\textsuperscript{1} for $B = 1.49$ M. Calculations
with the program LETAGROP give the new values $\log \beta_{1,2} = -6.30 \pm 0.09$
and $\log \beta_{2,4} = -19.19 \pm 0.02$ ($Z < 0.1$). The values of the equilibrium
constants must, however, be regarded as a kind of "average" values in the $Z$
range used in the calculations.

With the $Mg(ClO_4)_2$ data there is very good agreement between the calculated
and experimental data whereas the deviation found with $Ba(ClO_4)_2$ would call
for additional complexes for the higher values of $Z$. Let us assume that the
activity factors stay constant in a titration and limit the discussion to the
titrations with $B = 1.45$ M. The values of the $\beta$ would then be nearly the same.
The differences between the $Z$($\log h$) curves with NaClO$_4$ and BaClO$_4$$_2$ and
that with MgClO$_4$$_2$ suggest that the amount of the unknown species with
Ba(ClO$_4$)$_2$ would be ca. 10% and with NaClO$_4$ ca. 20% of the total amount
of lead hydrolysed. Since there is no evidence of these unknown species in
Mg(ClO$_4$)$_2$ one would estimate that the equilibrium constants of the unknown
species would be less by a factor of 10 in Mg(ClO$_4$)$_2$ as compared with the
other two media. This, however, seems very unlikely from the approximate
constancy of the values of the $\beta_{2,4}$ and $\beta_{1,2}$.

The deviations are the larger the larger is the value of $B$. This would require
that the unknown complexes have a ratio OH$^{-}$/Pb(II) $< 1$ (Ref.\textsuperscript{2}). Conceivable
complexes of this type, e.g. Pb$_4$(OH)$_5$$^2^+$, have values of $t$ smaller than the
experimental value 1.33. The relative positions of the \( Z(\log h)_B \) curves along
the log \( h \) axis do not therefore support the hypothesis that additional com-
plexes are formed.

Since the assumption of constant activity factors leads to a contradiction
with the experimental results we may conclude that the deviations are due to
variations of the activity factors, which at \( Z \approx 0.1 \) have become so large as
to interfere with the interpretation of the data. If mixed complexes between
the cation of the medium and \( \text{Pb}^{2+} \) and \( \text{OH}^- \) are formed these complexes
will, of course, interfere with the interpretation of the data in the self-medium
range. It is, however, unlikely that such complexes are formed since \( \beta_{4,4} \)
is found to be virtually constant despite changes in the medium and in addition
the tendency for \( \text{Ba}^{2+} \) and \( \text{Mg}^{2+} \) to associate with \( \text{OH}^- \) is very weak
\( n_{11,12} \).

The inference on the self-medium method which can be drawn from this
work would then be that reliable conclusions can be drawn only from the
range where \( Z \leq 0.05 \) with \( B > 1 \) M. Of course the limit set can claim no
general validity but may vary greatly from one system to another as shown
by the combination \( \text{Pb(ClO}_4)_2 + \text{Mg(ClO}_4)_2 \), where good results are obtained
at least up to \( Z = 0.25 \).

If "finger-prints" of the complexes could be obtained the question whether
new complexes are formed or not could be settled. Unfortunately this does
not seem possible at present. The Raman spectra of dilute solutions are not
sufficiently intense and good infrared spectra are difficult to obtain because
of the strong absorption of the water itself.

The same question again arises when attempts are made to determine
the structure of complexes in solution by means of X-ray diffraction. Such
studies are made with concentrated solutions and the interpretation of the
X-ray data is probably best made by correlating such data with a knowledge
of the composition of the complexes, as inferred from emf work.
