

The Crystal Structure of Strontium Diborate, $\text{SrO} \cdot 2\text{B}_2\text{O}_3$

J. KROGH-MOE

Svenska Silikatforskningsinstitutet, Göteborg, Sweden

Strontium diborate, $\text{SrO} \cdot 2\text{B}_2\text{O}_3$, crystallizes in the space group $Pmn2_1$, with unit cell dimensions: $a = 10.711 \pm 0.005 \text{ \AA}$, $b = 4.427 \pm 0.002 \text{ \AA}$, $c = 4.235 \pm 0.002 \text{ \AA}$ and two formula units in the cell, corresponding to a calculated density of 4.02 g/cm^3 . The crystal structure has been solved with two-dimensional Patterson and three-dimensional Fourier syntheses and refined with the method of least squares. A reliability index $R = 0.126$ was obtained for data from 189 three-dimensional reciprocal lattice points. The structure consists of a three-dimensional network of BO_4 -tetrahedra. Some of the oxygens in the structure are bonded to three borons.

As part of a general survey of anhydrous polyborate structures, the crystal structure of strontium diborate has been determined. The preceding paper in this series is concerned with the structure of silver tetraborate.¹ This compound obeyed the rule that the number of borons in four-fold coordination is equal to the number of foreign cation charges. The same coordination behaviour of boron was previously observed in a series of alkali borates with a high boron oxide content. Considering the small energy requirement for a coordination change of boron,² it cannot be assumed that the rule is of general validity, especially if other cations than alkali atoms are introduced. The present investigation has revealed a new case where the rule breaks down. Here we have a type of anomalous coordination behaviour related to that discovered by Clark³ in the hydrated borate mineral, tunnellite, $\text{SrO} \cdot 3\text{B}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$.

Recently X-ray data for strontium diborate have been published by Stewart and Rindone⁴, and by Block, Perloff and Weir.⁵ The unit cell dimensions given by the latter authors agree reasonably well with those reported here.

EXPERIMENTAL

Strontium diborate was crystallized around 900°C from a melt with a slight excess of boron oxide.

The following unit cell dimensions were determined with a least squares fit of powder diffraction data from a Hagg-Guinier camera, using lead nitrate as internal standard:

$$\begin{aligned} a &= 10.711 \pm 0.005 \text{ \AA} \\ b &= 4.427 \pm 0.002 \text{ \AA} \\ c &= 4.235 \pm 0.002 \text{ \AA} \end{aligned}$$

With 2 formula units of $\text{SrO:2B}_2\text{O}_3$ in the cell, the calculated density becomes 4.02 g/cm^3 . This is a relatively large value. However, by floating the sample in Clericis solution it was verified that the density was above 3.9 g/cm^3 and close to 4.0 g/cm^3 .

Single crystal integrated Weissenberg exposures were obtained with $\text{CuK}\alpha$ -radiation around the two shortest axes for the zeroth to second layer. Systematic extinction were observed for the $h0l$ reflections when $h + l = 2n + 1$, indicating one of the space groups $Pmn2_1$ and $Pm\bar{m}n$.

The crystal, which was rotated around the b -axis, had a quadratic cross-section $0.005 \times 0.005 \text{ cm}$ perpendicular to the axis of rotation and the crystal rotated around the c -axis had a corresponding cross-section $0.007 \times 0.0085 \text{ cm}$. The linear absorption coefficient is 200 cm^{-1} for $\text{CuK}\alpha$ -radiation, so that the absorption effects are not entirely negligible. No corrections for absorption were made, but a rough estimate of the effect will be given in the next paragraph.

Intensities were estimated visually from triple film packs by comparing the Weissenberg spots with a calibrated strip. After the Lorentz-polarization corrections, the intensities from the various layers around the two axes were adjusted so as to bring all the values on a common scale. For reciprocal lattice points, where two measurements were available, those from the smaller crystal were given a higher weight.

THE STRUCTURE DETERMINATION

The Patterson projections revealed a strontium—strontium vector incompatible with the special two-fold positions in the space group $Pm\bar{m}n$. It was therefore concluded that the correct space group is $Pmn2_1$. Based on information from the Patterson functions about the strontium position, a three-dimensional electron density distribution was calculated. The summation contained a false symmetry (since phases were obtained only from strontium positions) but peaks due to the false symmetry could be eliminated by considering interatomic distances. The structure thus obtained was refined to a reliability index of 12.6 % with the method of least squares, using the program written by Åsbrink and Brändén for the Facit computer. Absolute values of the calculated structure factors are given in Table 1 and the final atomic parameters are reported in Table 2. The atoms Sr and O_1 occupy special two-fold positions in the space group. The origin along the z -axis is arbitrarily fixed on the strontium atom.

From the two last columns given in Table 2, the strontium atom appears to have a significant negative temperature factor parameter $B = -0.67$. This is largely accounted for by absorption errors, however. If the crystal with cross-section $0.005 \times 0.005 \text{ cm}$ (respectively $0.007 \times 0.0085 \text{ cm}$) had been a cylinder with the same cross-sectional area, the absorption correction for the equatorial layer would, well within the accuracy of the intensity reading, correspond to multiplying the intensities with an artificial temperature factor with parameter value $2B = 0.4$ (respectively $2B = 0.6$)... Somewhat larger corrections are valid for the upper layers, and larger corrections also apply for certain planes in the equatorial layer of the quadratic or rectangular crystals. It is therefore reasonable to blame the absorption errors for the fact that the temperature factor parameter for strontium becomes negative in the least squares refinement.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

A projection of the structure along the a -axis is shown in Fig. 1. The structure consists of a three-dimensional network of BO_4 -tetrahedra. The

Fig. 1. Projection along the a -axis. Filled circles represent boron, open circles represent oxygen, large dashed circles represent strontium. The unit cell is indicated with dashed lines. Oxygens closest to strontium in projection form bridges with layers below or above, which are mirror images of the layer shown.

layer of BO_4 -tetrahedra, shown in the figure, is connected with its own mirror image exactly above or below through the atom O₁. The O₁ atom, seen closest to strontium in the projection, will thus appear in this projection as if it were bonded to only one boron. (O₁ atoms with z -parameters 0.454 connect with layers above, those with z -parameters 0.954 connect with layers below).

Table 3. Boron—oxygen bond distances and shortest strontium—oxygen distances, with standard deviations. Each of the tabulated distances from strontium to O₂, O₃, and O₄ occurs twice, so that strontium has 9 oxygen neighbours below 3 Å.

B ₁ — O ₁	1.37 ± 0.04 Å	Sr — O ₁	2.73 ± 0.07 Å
B ₁ — O ₂	1.47 ± 0.05		3.02 ± 0.07
B ₁ — O ₃	1.50 ± 0.06		3.14 ± 0.07
B ₁ — O ₄	1.55 ± 0.09		3.39 ± 0.07
B ₂ — O ₁	1.53 ± 0.06	Sr — O ₂	2.47 ± 0.03
B ₂ — O ₂	1.48 ± 0.06		2.90 ± 0.03
B ₂ — O ₃	1.61 ± 0.09	Sr — O ₃	3.09 ± 0.03
B ₂ — O ₄	1.38 ± 0.06		3.15 ± 0.03
		Sr — O ₄	2.68 ± 0.04
			2.79 ± 0.04

It is also seen from Fig. 1 that the structure contains six-membered boron-oxygen rings. Such rings are a very common feature in a wide variety of borate structures. The present structure may even be described as chains along the *c*-axis formed by these six-membered rings sharing edges. The chains are crosslinked with neighbouring chains at regular intervals.

The boron-oxygen bond lengths are given in Table 3. The average value of these bond lengths, 1.49 Å, is slightly larger than the average value of 1.47 Å found for BO₄-tetrahedra in several structures. The spread of the individual bond lengths about the average value cannot be considered significant (perhaps with the exception of the B₁—O₁ distance). It is not unlikely, however, that the BO₄-tetrahedra could be somewhat distorted.

The atom O₃ is remarkable inasmuch as it is bonded to three boron atoms. This situation is not quite unique, however. Structures with oxygens three-fold coordinated by boron have been reported for hexagonal boron oxide by Berger⁶ and recently for the mineral tunellite, SrO·3B₂O₃·4H₂O, by Clark.³ Three-bonding oxygens with two bonds to boron and a third to hydrogen are known from some metaboric acids.⁷ In the present structure the average of the three bond distances to O₃ (1.53 Å) seems to be somewhat larger than the average of the remaining boron-oxygen distances (1.46 Å). The available data are not sufficiently accurate to establish this lengthening with certainty, but a similar lengthening of the boron-oxygen bond for three-fold coordinated oxygen has been indicated by the study of tunellite.³

The coordination of strontium by oxygen is definitely irregular. An irregular cation coordination has previously been observed in other anhydrous borates.¹ It is therefore difficult to establish a meaningful value for the coordination number of the cation in these phases. Table 3 lists values for the 16 shortest strontium-oxygen distances ranging upwards from 2.74 Å to 3.39 Å. The sum of the ionic radii of strontium and oxygen is 2.35 Å. Setting an arbitrary limit at 2.90 Å for the first coordination sphere of strontium, a coordination number of 9 follows. It is interesting to note that the three-fold coordinated oxygen is comparatively far removed (3.09 Å or more) from strontium.

The structure reported here demonstrates the precarious balance of boron between the coordination numbers three and four. This circumstance has previously been emphasized by the author, *e.g.* it has been proposed that the comparatively low viscosity of molten boron oxide is due to the low energy required for activating states with four-fold coordinated boron and three-fold coordinated oxygen.⁸
