Hydrated rare earth methanesulfonates react with 3-picoline-N-oxide (3-picNO) to form isomorphous compounds of composition Ln(CH₃SO₃)₂ · 2(3-picNO), where Ln is La–Lu, Y (excl. Pm). IR spectra indicate that the methanesulfonate anions and the 3-picNO ligands are involved in coordination to the rare earth ion. Thermal decomposition studies in air and nitrogen under different experimental conditions show that anhydrous rare earth methanesulfonates are formed when the 3-picNO ligands are expelled. Further heating in air in the temperature range 400–900°C produces the dioxosulfate, Ln₂O₃SO₄, but in nitrogen the decomposition leads to the formation of dioxodisulfide, Ln₂O₃S₂, which then decomposes to dioxosulfide, Ln₂O₃S. The cerium complex decomposes in air directly to CeO₂ without formation of the oxosulfate intermediate.

Charbonnier and coworkers have recently investigated the interesting thermal behaviour of several methanesulfonate compounds formed by main group and transition metals.1–7 Similar detailed data are not available for the rare earth methanesulfonates, which can have, besides the Ln(CH₃SO₃)₂-type,8,9 a more complex composition if additional ligands are available for coordination. Some complexes in the series Ln(CH₃SO₃)₂ · 3TMSO (TMSO = tetramethylene sulfoxide) have been characterized by thermogravimetric measurements.10

In this paper we report the results of a mainly thermoanalytical study of a new series of methanesulfonate complexes with 3-picoline-N-oxide (3-picNO). A thermogravimetric study on rare earth methanesulfonate hydrates is also in progress.11

Experimental

Materials. The compounds were prepared by mixing 3-picNO with the hydrated rare earth methanesulfonate in a molar ratio of 3:1.8,12 After gently heating the mixture for a few minutes, an oily mass was obtained which was treated with an equal volume of acetone under agitation with a glass rod. In some cases crystallization took place immediately, while in other cases a few days elapsed. The mixture was left to stand for approximately one week to complete the crystal formation. The crystals were then collected, washed with acetone and dried in vacuo over anhydrous calcium chloride. Similar results were obtained when triethylothioformate or 2,2-dimethoxypropane were used instead of acetone.

The rare earth content of the complexes was determined by complexometric titration with EDTA, and the C, H and N analyses were performed by standard microanalytical techniques. Melting ranges were also determined and they varied from 244–248°C (La) to 115–119°C (Yb).

Methods. X-ray powder diffraction patterns were obtained using a Noreco instrument with CuK\(_\alpha\) radiation. IR spectra of the compounds were recorded on a Perkin-Elmer 283 spectrophotometer using nujol mulls between KBr plates.

Thermogravimetric studies were performed with Perkin-Elmer TGS-2 or TGA-7 instruments equipped with a controller unit and coupled to a computer for the evaluation of the data. Three series of TG runs were performed for all samples (La–Lu, Y) in a dynamic atmosphere as follows: (i) 1 °C min\(^{-1}\) in air, (ii) 1 °C min\(^{-1}\) in N\(_2\), and (iii) 10 °C min\(^{-1}\) in N\(_2\). Standard platinum crucibles were used and the sample weight was approximately 5 mg. In addition, several other experimental conditions, including isothermal heating in air and in nitrogen, were tried in individual cases.

Results and discussion

Characterization. Analytical data are consistent with the general formula \( \text{Ln}(\text{CH}_3\text{SO}_3)_3 \cdot 2(\text{3-picNO}) \) for all compounds (Ln = La–Lu, Y). X-ray powder diffraction data indicate that they are isomorphous.

methanol, and from the IR spectra, it is clear that both the methanesulfonate and the 3-picNO ligands are involved in coordination to the lanthanoid ion. This is in contrast with the behaviour of lanthanoid 4-picNO complexes with trifluoromethanesulfonate, where the weakly coordinating trifluoromethanesulfonate ligand remains outside the inner coordination sphere.$^{13,14}$ The N–O stretching vibration could not be unequivocally distinguished from the asymmetric S–O stretching band since they both occur in the same region (Table 1). It is certain, however, that the N–O band is shifted towards lower frequencies. The splitting of the asymmetric S–O stretching band indicates lowering of the symmetry through coordination of the CH$_3$SO$_3^-$ anion, probably in a bidentate or bridging mode. The emission spectrum of the europium compound indicates that the most probable point group symmetry is C$_{3v}$.$^{12}$

Thermal decomposition. The first step in the thermal degradation process, both in air and nitro-
gen, is the loss of the 3-picNO ligands. This starts at 150–200°C and is complete some 100–150°C higher, the exact temperatures depending on experimental conditions and on the nature of the rare earth ions (Figs. 1–3). When a low heating rate (1°C min⁻¹) is employed, the loss of the 3-picNO ligands takes place in a single step for the lighter rare earths (La–Gd), while for the heavier lanthanoids and yttrium it is a two-step process. With a 10°C min⁻¹ heating rate, all rare earths except lanthanum and cerium decompose in a multi-step fashion. The intermediate phase does not, however, correspond to the loss of 1 mol of 3-picNO, the observed values under these experimental conditions ranging from 0.4 to 0.8 mol depending on the nature of the rare earth ion (Fig. 3).

The anhydrous lanthanoid methanesulfonates are stable in air up to 350–400°C where rapid decomposition begins followed, above 500°C, by a much slower process. In the case of lanthanum and cerium, the decomposition rate above 500°C is first minimal but increases again above 700–800°C (Figs. 1 and 2). The end product below 1000°C for all rare earths except cerium is the dioxosulfate, Ln₂O₂SO₄ (Figs. 1, 3), as is the case with the rare earth sulfates.¹⁷ The oxosulfate is stable over a wide temperature range, especially for the lighter lanthanoids, and its decomposition produces the sesquioxide, usually at temperatures well above 1000°C.¹⁸ In the case of cerium, the oxosulfate intermediate is not present, and formation of CeO₂ is complete at 750°C (Fig. 2).

The interpretation of the TG curves for N₂ atmosphere is not straightforward. The fast reaction step around 400°C converts the anhydrous methanesulfonate to an intermediate phase which then slowly decomposes to the final product, which is not Ln₂O₂SO₄ but Ln₂O₂S. Fig. 4 depicts the thermal degradation of the Nd complex as a typical example. The formation of lanthanoid dioxosulfide instead of dioxosulfate was ascertained by an X-ray diffraction analysis and by measuring the weight change occurring when the residue was heated in air and converted to dioxosulfate.¹⁹ The calculated and observed weight changes for decomposition of Nd(CH₃SO₃)₂·2(3-picNO) to Nd₂O₂SO₄ are 68.5 and 68.4%, respectively (Fig. 5).

The observed weight loss at the intermediate level in nitrogen corresponds not only to formation of Ln₂S₃,¹⁰ but also to the formation of Ln₂O₂S₂. The molecular weights and thereby the theoretical weight losses are initially identical; for instance, in the case of La₂S₃ and La₂O₂S₂ the molecular weights are 373.99 and 373.93, respectively. The La₂O₂S₂ alternative was considered more plausible for the following reasons: (i) the formation of Ln₂O₂S from Ln₂O₂S₂ is facile and does not require the presence of oxygen, (ii) the observed stability range of Ln₂O₂S₂ corresponds well with the temperatures used for its synthesis,²⁰ and (iii) the formation of Ln₂O₂S₂ from Ln(CH₃SO₃)₃ does not require complete breakdown of the Ln–O bond system which is known from X-ray crystal structure determinations to be

present in related sulfonate compounds.\textsuperscript{21} Even the cerium compound appears to follow this decomposition mechanism, although the stability of the \( \text{Ce}_2\text{O}_5\text{S}_2 \) phase is very limited (Fig. 6).

It is interesting to compare the thermal behaviour of the lanthanoid compounds with those of other transition metal (M) methanesulfonates.\textsuperscript{6} It appears that in an inert atmosphere — depending on the relative strengths of the M–S and M–O bonds and on the M\textsuperscript{n+}/M oxidation potential — elemental metal, binary sulfide, oxide, or a mixture thereof, may form. As the trivalent rare earth ions are hard acids or a-type ions, and thus have a preference for forming strong bonds with oxygen,\textsuperscript{22} it is not surprising that the lanthanoid methanesulfonates adopt a reaction route via the dioxodisulfide to the stable dioxosulfide. This interesting sequence of thermal reactions offers new possibilities for the synthesis of rare earth oxosulfides,\textsuperscript{12} which are known for their important technical applications as phosphor materials.\textsuperscript{23}
